Physical feasibility of robot base inertial parameter identification: A linear matrix inequality approach

Cristóvão D. Sousa and Rui Cortesão

Abstract

Identification of robot dynamics is a key issue in boosting the performance of model-based control techniques, having also a key role in realistic simulation. Robot dynamic parameters have physical meaning, hence parameter estimations must correspond to physically feasible values. Since it is only possible to identify linear combinations of parameters (the base parameters) the physical feasibility of such combinations cannot be directly asserted. In this paper we show that feasibility conditions define a convex set and can be written as a linear matrix inequality (LMI), suitable for semidefinite programming (SDP) techniques. We propose three methods based on LMI–SDP to deal with the feasibility of base parameters. The first method checks if a given base parameter estimation has physical meaning. The second method corrects infeasible estimations, finding the closest feasible base parameters. These two methods can be applied to existing regression techniques. The third method performs parameter identification through ordinary least squares regression constrained to the feasible space, guaranteeing the optimal solution. Experiments with a seven-link robot manipulator are provided, and efficiency and scalability are discussed.

Keywords

Dynamics, calibration, identification, physical feasibility, physical consistency, mechanics, control

1. Introduction

The knowledge of robot dynamics is essential to boosting model-based control, enabling high performance motions and controlled force interactions. Moreover, accurate dynamic models are also important for realistic robot simulation. Robot dynamics depends on both geometry and rigid-body parameters, including link inertia, and friction. The identification of dynamic parameters can be done through computer-aided design (CAD) software, by individual experimental tests of robot parts, or by dynamic model regression methods. Since the robot dynamic model is linear with respect to inertial parameters, linear regression techniques can be applied, although some parameters can only be estimated in linear combinations, known as base parameters (Gautier and Khalil, 1990). There is a rich literature on parameter identification, focusing on regression uncertainties and excitation trajectories: see Wu et al. (2010) for an overview. Notwithstanding all the research, the physical feasibility of estimated parameters is often disregarded. Dynamic parameters have physical meaning and are therefore bounded to physical values. Nevertheless, the verification of physical consistency of base parameters is not straightforward. Physically infeasible estimations lead to non-positive inertia matrices at some, or even all, joint positions. Consequently, such dynamic models lead

to unrealistic simulation and unstable model-based control (Yoshida and Khalil, 2000). It can be argued that adequate experiments can lead to estimations that are accurate enough to be physically feasible. However, no matter how good the parameter excitation and regression techniques are, a mathematical proof that guarantees physical feasibility of robot base inertia parameter estimation is necessary. Moreover, a regression method constrained to physically feasible solutions can be of interest. Yoshida and Khalil (2000) proposed a trial and error recursive method to check if a base parameter estimation is feasible using two-dimensional graphs. It is unclear if this method is suited to automatic implementation or if it is capable of coping with a high number of robot links. Mata et al. (2005) proposed a method for parameter identification taking feasibility into account. The method first finds an unconstrained base parameter estimation using classical regression. Then, a quadratic programming optimization constrained to feasible values is done over the total inertial parameters, minimizing

both the regression error and the distance to the base parameters previously found. The method presents a variable to be tuned between two optimization objectives, and the convergence to the global solution that minimizes regression error is not discussed. Ting et al. (2011) proposed a nonlinear Bayesian parameter identification method with physical feasibility assessment. Feasibility is guaranteed by searching for a solution in a feasible virtual parameter space which has a nonlinear projection onto the inertial parameter space. This solution is the one closest to the unconstrained solution, where the distance is weighted by regression data. Ayusawa and Nakamura (2010) proposed an identification method for a high number of link robots addressing physical feasibility. By representing robot links as a finite number of mass points they replace the feasibility conditions by linear inequalities. In this way the optimization is simplified, although the quality of the approximation depends on the number of mass points. Díaz-Rodríguez et al. (2010) proposed an approach where less significant parameters are pruned from the model until the identified ones are feasible. Feasibility is checked by searching the overall discretized solution space. Gautier et al. (2013) proposed a method where the regression estimation is pushed towards an a priori known feasible solution obtained from CAD data. The feasibility is then checked by taking into account a tolerance to accommodate regression data measurement errors.

In our paper, we show that physical feasibility conditions can be written in a semidefinite programming (SDP) perspective, as a linear matrix inequality (LMI). This implies that the set defined by physical feasibility conditions is necessarily convex, leading to global optimums in optimization problems. It follows that base parameters can also be written as LMIs. This allows the development of SDP problems to treat physical feasibility constraints. SDP techniques are known for being effective and fast, allowing problems with a high number of parameters to be efficiently solved. We first present a succinct SDP-based method which verifies base parameter feasibility in an automatic and scalable fashion. Then, we devise a method to correct infeasible parameter solutions to the closest feasible one. Furthermore, we propose a regression method which finds the optimal physically feasible base parameter solution that best fits the regression data.

The paper is organized as follows. Section 2 introduces the conditions for physical feasibility of inertial parameters. In Section 3 we reformulate those conditions as an LMI. It is also shown how additional constraints can be included in the LMI formulation. In Section 4 we devise the feasibility test and correction methods for base parameters. Additionally, optimal base parameter feasibility estimation through constrained regression is proposed. In Section 5, two experiments are analyzed. The first one addresses the feasibility test in a three-link robot and the second one assesses the three proposed methods in a seven-link WAM robot. Section 6 concludes the paper.

2. Physical feasibility of inertial parameters

Rigid-body robot manipulator dynamics relates joint positions, velocities and accelerations (\mathbf{q} , $\dot{\mathbf{q}}$ and $\ddot{\mathbf{q}}$), with the joint generalized force/torque $\boldsymbol{\tau}$,

$$\mathbf{M}(\mathbf{q}) \ddot{\mathbf{q}} + \mathbf{c}(\mathbf{q}, \dot{\mathbf{q}}) + \mathbf{g}(\mathbf{q}) = \boldsymbol{\tau} \quad (1)$$

where $\mathbf{M}(\mathbf{q})$ is the mass matrix, which is symmetric and positive definite, $\mathbf{c}(\mathbf{q}, \dot{\mathbf{q}})$ represents Coriolis and centripetal forces and $\mathbf{g}(\mathbf{q})$ is the gravity term. All these terms depend on geometric and dynamic parameters. Each robot link contributes with a set of inertial parameters, composed by mass, center of mass and inertia tensor. Other dynamic parameters can also be taken into account, such as joint friction and actuator inertia. Dynamic parameters have physical restrictions which should be addressed in the estimation problem. Link masses are positive and inertia tensors are symmetric and positive definite. The set of conditions for each link k which guarantees physical feasibility is given by (Yoshida and Khalil, 2000)

$$\begin{cases} m_k > 0 \\ \mathbf{I}_k > 0 \end{cases} \quad (2)$$

where m_k is the link mass, the notation $\mathbf{A} > 0$ means that \mathbf{A} is positive definite and \mathbf{I}_k is the link inertia tensor about its center of mass,

$$\mathbf{I}_k \equiv \begin{bmatrix} I_{k,xx} & I_{k,xy} & I_{k,xz} \\ I_{k,xy} & I_{k,yy} & I_{k,yz} \\ I_{k,xz} & I_{k,yz} & I_{k,zz} \end{bmatrix} \quad (3)$$

Inertial parameters are often estimated using linear regression techniques; therefore the inertia tensor calculated about the link frame k , \mathbf{L}_k ,

$$\mathbf{L}_k \equiv \begin{bmatrix} L_{k,xx} & L_{k,xy} & L_{k,xz} \\ L_{k,xy} & L_{k,yy} & L_{k,yz} \\ L_{k,xz} & L_{k,yz} & L_{k,zz} \end{bmatrix} \quad (4)$$

has to be used instead of \mathbf{I}_k (Khalil and Dombre, 2002). Considering that link and center-of-mass frames are parallel, the relation between \mathbf{L}_k and \mathbf{I}_k , given by the Huygens–Steiner theorem, is

$$\mathbf{L}_k = \mathbf{I}_k + m_k \mathbf{S}(\mathbf{r}_k)^T \mathbf{S}(\mathbf{r}_k) \quad (5)$$

where $\mathbf{S}(\cdot)$ is the skew-symmetric matrix operator,

$$\mathbf{S}(\mathbf{x}) \equiv \begin{bmatrix} 0 & -x_3 & x_2 \\ x_3 & 0 & -x_1 \\ -x_2 & x_1 & 0 \end{bmatrix} \quad \text{for } \mathbf{x} \equiv \begin{bmatrix} x_1 \\ x_2 \\ x_3 \end{bmatrix} \quad (6)$$

The vector given by

$$\mathbf{r}_k \equiv \begin{bmatrix} r_{k,x} \\ r_{k,y} \\ r_{k,z} \end{bmatrix} \quad (7)$$

is the center of mass relative to the link frame k . The matrix \mathbf{L}_k is positive definite since it is the sum of a positive definite matrix and a positive semidefinite matrix. Furthermore, to apply linear regression techniques, the first moment-of-inertia vector, \mathbf{l}_k ,

$$\mathbf{l}_k \equiv \begin{bmatrix} l_{k,x} \\ l_{k,y} \\ l_{k,z} \end{bmatrix} = m_k \mathbf{r}_k = \begin{bmatrix} m_k r_{k,x} \\ m_k r_{k,y} \\ m_k r_{k,z} \end{bmatrix} \quad (8)$$

has to be used instead of \mathbf{r}_k (Khalil and Dombre, 2002). From (8) and (5), and knowing that $m_k > 0$, we get

$$\mathbf{L}_k = \mathbf{I}_k + m_k \mathbf{S} \left(\frac{\mathbf{l}_k}{m_k} \right)^T \mathbf{S} \left(\frac{\mathbf{l}_k}{m_k} \right) \quad (9)$$

Since $\mathbf{S}(\cdot)$ is a linear operator, (9) can be rewritten as

$$\mathbf{I}_k = \mathbf{L}_k - \frac{1}{m_k} \mathbf{S}(\mathbf{l}_k)^T \mathbf{S}(\mathbf{l}_k) \quad (10)$$

The set of all physical feasibility constraints for each link k given by (2) can then be written as

$$\begin{cases} m_k > 0 \\ \mathbf{L}_k - \frac{1}{m_k} \mathbf{S}(\mathbf{l}_k)^T \mathbf{S}(\mathbf{l}_k) \succ 0 \end{cases} \quad (11)$$

The vector $\boldsymbol{\delta}$ of all inertial parameters of a serial robot with N links is given by

$$\boldsymbol{\delta} \equiv [\boldsymbol{\delta}_1^T \boldsymbol{\delta}_2^T \dots \boldsymbol{\delta}_k^T \dots \boldsymbol{\delta}_N^T]^T \quad (12)$$

where, for each link k ,

$$\boldsymbol{\delta}_k \equiv [L_{k,xx} \ L_{k,xy} \ L_{k,xz} \ L_{k,yy} \ L_{k,yz} \ L_{k,zz} \ l_{k,x} \ l_{k,y} \ l_{k,z} \ m_k]^T \quad (13)$$

The vector $\boldsymbol{\delta}$ is the link inertial parameter vector (link parameter vector for short) (Yoshida and Khalil, 2000) and, from (12) and (13), has size $n = 10N$. The set of all physically feasible link parameter vectors, \mathcal{D} , can then be defined as

$$\mathcal{D} \equiv \{ \boldsymbol{\delta} \in \mathbb{R}^n : m_k > 0, \mathbf{L}_k - m_k^{-1} \mathbf{S}(\mathbf{l}_k)^T \mathbf{S}(\mathbf{l}_k) \succ 0 \mid k = 1, \dots, N \} \quad (14)$$

Making use of Sylvester's criterion, the constraints of (14) can be written as a system of polynomial inequalities in $\boldsymbol{\delta}$. Therefore, \mathcal{D} is a semialgebraic set.

3. Physical feasibility of inertial parameters as an LMI

This section addresses the physical feasibility of robot links, showing that \mathcal{D} is a convex set since it can be defined in the framework of LMIs, a common representation in control theory and in SDP.

3.1. Physical feasibility of each robot link

For each robot link, the second inequality of (11) can be written as a quadratic matrix inequality,

$$\mathbf{L}_k - \mathbf{S}(\mathbf{l}_k)^T (m_k \mathbf{1})^{-1} \mathbf{S}(\mathbf{l}_k) \succ 0 \quad (15)$$

where $\mathbf{1}$ is the identity matrix of proper size (size three, in this case). Through the Schur complement condition for positive definite matrices (Boyd et al., 1994; Goldman and Ramana, 1995), we can state that constraint (11) is equivalent¹ to

$$\begin{bmatrix} \mathbf{L}_k & \mathbf{S}(\mathbf{l}_k)^T \\ \mathbf{S}(\mathbf{l}_k) & m_k \mathbf{1} \end{bmatrix} \succ 0 \quad (16)$$

Defining the matrix $\bar{\mathbf{D}}_k(\boldsymbol{\delta}_k)$ as

$$\bar{\mathbf{D}}_k(\boldsymbol{\delta}_k) \equiv \begin{bmatrix} \mathbf{L}_k & \mathbf{S}(\mathbf{l}_k)^T \\ \mathbf{S}(\mathbf{l}_k) & m_k \mathbf{1} \end{bmatrix} = \begin{bmatrix} L_{k,xx} & L_{k,xy} & L_{k,xz} & 0 & -l_{k,z} & l_{k,y} \\ L_{k,xy} & L_{k,yy} & L_{k,yz} & l_{k,z} & 0 & -l_{k,x} \\ L_{k,xz} & L_{k,yz} & L_{k,zz} & -l_{k,y} & l_{k,x} & 0 \\ 0 & l_{k,z} & -l_{k,y} & m_k & 0 & 0 \\ -l_{k,z} & 0 & l_{k,x} & 0 & m_k & 0 \\ l_{k,y} & -l_{k,x} & 0 & 0 & 0 & m_k \end{bmatrix} \quad (17)$$

(16) is an LMI since it can be written as

$$\bar{\mathbf{D}}_k(\boldsymbol{\delta}_k) \succ 0 \quad (18)$$

with

$$\bar{\mathbf{D}}_k(\boldsymbol{\delta}_k) \equiv \mathbf{D}_0 + \sum_{j=1}^{10} \mathbf{D}_{k,j} \delta_{k,j} \quad (19)$$

where \mathbf{D}_0 and $\mathbf{D}_{k,j}$ are 6×6 symmetric matrices, and each $\delta_{k,j}$ is one element of $\boldsymbol{\delta}_k$ (see (13)). The matrix $\bar{\mathbf{D}}_k(\boldsymbol{\delta}_k)$ is equivalent to the generalized inertia of the recursive formulation of robot dynamics using Lie groups proposed by Park et al. (1995). There are similar representations in other dynamic formulations related to screw theory and using 6D vector forms of robot motion and forces, such as the spatial vectors of Featherstone (2010). Equation (18) is a strict LMI since $\bar{\mathbf{D}}_k(\boldsymbol{\delta}_k)$ is strictly positive definite. In a practical approach we can say that (18) is equivalent to the nonstrict LMI

$$\mathbf{D}_k(\boldsymbol{\delta}_k) \succeq 0 \quad (20)$$

where the notation $\mathbf{A} \succeq 0$ means that \mathbf{A} is positive semidefinite, with

$$\mathbf{D}_k(\boldsymbol{\delta}_k) \equiv \bar{\mathbf{D}}_k(\boldsymbol{\delta}_k) - \varepsilon \mathbf{1} \quad (21)$$

where ε is an infinitesimally small positive scalar. We will use the nonstrict LMI formulation since it is required for SDP.

3.2. Physical feasibility of a robot with N links

For a robot with N links, the feasibility condition can be expressed as

$$\mathbf{D}(\delta) \geq 0 \quad (22)$$

where $\mathbf{D}(\delta)$ is a single block-diagonal matrix given by

$$\mathbf{D}(\delta) \equiv \begin{bmatrix} \mathbf{D}_1(\delta_1) & \mathbf{0} & \cdots & \mathbf{0} \\ \mathbf{0} & \mathbf{D}_2(\delta_2) & \cdots & \mathbf{0} \\ \vdots & \vdots & \ddots & \vdots \\ \mathbf{0} & \mathbf{0} & \cdots & \mathbf{D}_N(\delta_N) \end{bmatrix}_{6N \times 6N} \quad (23)$$

The set \mathcal{D} of (14) can then be rewritten as

$$\mathcal{D} = \{\delta \in \mathbb{R}^n : \mathbf{D}(\delta) \geq 0\} \quad (24)$$

This set is a spectrahedron since it is representable by a nonstrict LMI. Like all spectrahedra, \mathcal{D} is convex. Spectrahedra are the solution spaces of semidefinite programs, which, remarkably, are guaranteed to converge to the global optimum and can be solved very efficiently (Vandenberghe and Boyd, 1996).

3.3. Additional constraints and additional dynamic parameters

The set of conditions discussed above guarantee a physically feasible dynamic model. However, the defined feasibility region can be further shrunk to only include solutions respecting particular robot specifications. For example, one can consider upper and lower limits for link masses $m_{k,l}$ and $m_{k,u}$ respectively,

$$\begin{cases} m_k - m_{k,l} \geq 0 \\ -m_k + m_{k,u} \geq 0 \end{cases} \quad (25)$$

Constraints on the sum of link masses can also be added. Furthermore, since link centers of mass have to be within link convex hulls, one can consider the constraints

$$\begin{cases} l_k - m_k r_{k,l} \geq 0 \\ -l_k + m_k r_{k,u} \geq 0 \end{cases} \quad (26)$$

for a cuboid-shaped link, or even constraints for other shapes (e.g. cylindrical). Moreover, it is usual to include additional dynamic effects in the model, such as driver chain friction and inertia. For each joint k , friction is often modeled as

$$f_k = f_{vk} \dot{q}_k + f_{ck} \operatorname{sgn}(\dot{q}_k) + f_{ok} \quad (27)$$

where f_{vk} and f_{ck} are positive constant parameters for viscous and Coulomb friction, respectively, and f_{ok} is the Coulomb friction offset which can also include a motor current offset. The drive chain inertia seen by joint k can be represented by a positive constant I_{ak} . When taken into account, these parameters are included in the δ vector, and

positiveness conditions can be included in the feasibility set. Adding more constraints is as simple as appending additional LMI blocks to the diagonal of $\mathbf{D}(\delta)$. For example, for friction and drive inertia positiveness constraints, one can define an LMI matrix as

$$\mathbf{D}_{\text{ext}}(\delta) = \operatorname{diag}(\mathbf{D}(\delta), f_{v1}, f_{c1}, I_{a1}, \dots, f_{vN}, f_{cN}, I_{aN}) \quad (28)$$

Indeed, a large range of simple and complex conditions can be easily cast into the LMI formulation (Boyd et al., 1994).

4. Physical feasibility of base inertial parameters

Given some δ estimate, $\hat{\delta}$, the verification of its physical feasibility is a matter of checking if $\hat{\delta}$ is in \mathcal{D} . This is done in straightforward way by numerically checking the positive definiteness of $\mathbf{D}(\hat{\delta})$. Since the parameter estimation has to be done in base inertial parameters (Gautier and Khalil, 1990; Mayeda et al., 1990) rather than in the link inertial parameter space δ , further methodologies are necessary. In the sequel, we propose a new method taking advantage of SDP, yielding easy, fast and automatic implementation.

4.1. Base inertial parameter formulation

It is well known that robot dynamics is linear to δ ,

$$\mathbf{H}(q, \dot{q}, \ddot{q}) \delta = \tau \quad (29)$$

where the matrix \mathbf{H} has a structure such that some of its columns are always null and others are always linearly dependent (Khalil and Dombre, 2002). Hence, (29) can be reduced to a minimum number, n_b , of linearly independent columns. Reordering, (29) can be written as

$$[\mathbf{H}_b \quad \mathbf{H}_d] [\delta_b^T \quad \delta_d^T]^T = \tau \quad (30)$$

where \mathbf{H}_b has n_b linearly independent columns of \mathbf{H} , and \mathbf{H}_d has the n_d remaining null and dependent columns, with

$$n = n_b + n_d \quad (31)$$

The matrix \mathbf{H}_d can be written as a linear combination of \mathbf{H}_b ,

$$\mathbf{H}_d = \mathbf{H}_b \mathbf{K}_d \quad (32)$$

where \mathbf{K}_d is a constant matrix. Vectors δ_b and δ_d are reordered link inertial parameters according to \mathbf{H}_b and \mathbf{H}_d . Equations (30) and (29) are related by

$$\begin{aligned} \mathbf{H}_b &\equiv \mathbf{H} \mathbf{P}_b \\ \mathbf{H}_d &\equiv \mathbf{H} \mathbf{P}_d \\ \delta_b &\equiv \mathbf{P}_b^T \delta \\ \delta_d &\equiv \mathbf{P}_d^T \delta \end{aligned} \quad (33)$$

where \mathbf{P}_b and \mathbf{P}_d are, respectively, the n_b first columns and the n_d last columns of a permutation matrix \mathbf{P} which verifies

$$\mathbf{H} \mathbf{P} = [\mathbf{H}_b \quad \mathbf{H}_d] \quad (34)$$

The column selection for the basis \mathbf{H}_b is not unique, but it is usual to choose the first independent columns of \mathbf{H} starting from the left. Equation (30) can then be written as

$$\mathbf{H}_b \boldsymbol{\beta} = \boldsymbol{\tau} \quad (35)$$

where $\boldsymbol{\beta}$ is the base inertial parameter vector (of size n_b),

$$\boldsymbol{\beta} \equiv [\beta_1 \quad \beta_2 \quad \cdots \quad \beta_{n_b}]^T \quad (36)$$

which is equal to a linear combination of link parameters $\boldsymbol{\delta}$,

$$\boldsymbol{\beta} = \boldsymbol{\delta}_b + \mathbf{K}_d \boldsymbol{\delta}_d \quad (37)$$

The matrices \mathbf{P}_b , \mathbf{P}_d and \mathbf{K}_d can be obtained either by rule-based (Gautier and Khalil, 1990; Mayeda et al., 1990) or numerical-based methods (Gautier, 1991). From (33), (37) can also be written as

$$\boldsymbol{\beta} = \mathbf{K} \boldsymbol{\delta} \quad (38)$$

with

$$\mathbf{K} = \mathbf{P}_b^T + \mathbf{K}_d \mathbf{P}_d^T \quad (39)$$

4.2. Base inertial parameter feasible set

Equation (38) defines a linear map from the $\boldsymbol{\delta}$ (\mathbb{R}^n) to $\boldsymbol{\beta}$ (\mathbb{R}^{n_b}) spaces. This is not a bijective map, therefore for each $\hat{\boldsymbol{\beta}}$ vector picked from the $\boldsymbol{\beta}$ space, there is more than one solution in the $\boldsymbol{\delta}$ space. Yoshida and Khalil (2000) called this set of $\boldsymbol{\delta}$ solutions the *virtual parameters* of $\hat{\boldsymbol{\beta}}$, which can be defined by $\mathcal{V}_{\hat{\boldsymbol{\beta}}}$,

$$\mathcal{V}_{\hat{\boldsymbol{\beta}}} \equiv \{\boldsymbol{\delta} \in \mathbb{R}^n : \mathbf{K} \boldsymbol{\delta} = \hat{\boldsymbol{\beta}}\} \quad (40)$$

Yoshida and Khalil have shown that if there is at least one feasible $\boldsymbol{\delta}$ vector in the virtual parameter set $\mathcal{V}_{\hat{\boldsymbol{\beta}}}$ (i.e. if $\mathcal{V}_{\hat{\boldsymbol{\beta}}}$ intersects \mathcal{D}), then the respective $\hat{\boldsymbol{\beta}}$ defines a positive definite robot inertia matrix, meaning that $\hat{\boldsymbol{\beta}}$ is physically feasible. Therefore we can define the set of all physically feasible base parameters, \mathcal{B} , as

$$\mathcal{B} \equiv \{\boldsymbol{\beta} \in \mathbb{R}^{n_b} : \exists \boldsymbol{\delta} \in \mathcal{D} \mid \mathbf{K} \boldsymbol{\delta} = \boldsymbol{\beta}\} \quad (41)$$

This definition cannot be directly used to verify if a given $\hat{\boldsymbol{\beta}}$ vector is in \mathcal{B} since \mathbf{K} is not square, and there is an existential quantifier (\exists) over a continuous set. Below, we reformulate (41) in a semidefinite representation to overcome this problem. Although $\boldsymbol{\beta} = \mathbf{K} \boldsymbol{\delta}$ is not bijective, it is possible to define a bijective mapping. A new map \mathbf{m} with $\boldsymbol{\delta}$ as domain and $(\boldsymbol{\beta}, \boldsymbol{\delta}_d)$ as codomain can be defined by

$$\begin{aligned} \mathbf{m} : \mathbb{R}^n &\rightarrow \mathbb{R}^n \\ \boldsymbol{\delta} &\rightarrow (\boldsymbol{\beta}, \boldsymbol{\delta}_d) \end{aligned} \quad (42)$$

where

$$\mathbf{m}(\boldsymbol{\delta}) \equiv \mathbf{G} \boldsymbol{\delta} \quad (43)$$

and

$$\mathbf{G} \equiv \mathbf{K}_G \mathbf{P}^T \quad (44)$$

with

$$\mathbf{K}_G \equiv \begin{bmatrix} \mathbf{1} & \mathbf{K}_d \\ \mathbf{0} & \mathbf{1} \end{bmatrix} \quad (45)$$

Multiplying \mathbf{G} by $\boldsymbol{\delta}$,

$$\begin{aligned} \mathbf{G} \boldsymbol{\delta} &= \mathbf{K}_G \mathbf{P}^T \boldsymbol{\delta} \\ &= \begin{bmatrix} \mathbf{1} & \mathbf{K}_d \\ \mathbf{0} & \mathbf{1} \end{bmatrix} \begin{bmatrix} \boldsymbol{\delta}_b \\ \boldsymbol{\delta}_d \end{bmatrix} \\ &= \begin{bmatrix} \boldsymbol{\beta} \\ \boldsymbol{\delta}_d \end{bmatrix} \equiv (\boldsymbol{\beta}, \boldsymbol{\delta}_d) \end{aligned} \quad (46)$$

Since \mathbf{P}^T is a permutation matrix and \mathbf{K}_G is upper triangular with non-zero diagonal elements, it follows that \mathbf{G} is invertible, and hence the map \mathbf{m} is bijective. Therefore, there is a one-to-one correspondence between extended base parameters $(\boldsymbol{\beta}, \boldsymbol{\delta}_d)$ and link parameters $\boldsymbol{\delta}$. Since Goldman and Ramana (1995) proved that a spectrahedral set remains spectrahedral if a bijective affine transformation is applied, a new physically feasible extended base parameter set, $\mathcal{D}_{\boldsymbol{\beta}}$, can be defined as

$$\mathcal{D}_{\boldsymbol{\beta}} \equiv \{(\boldsymbol{\beta}, \boldsymbol{\delta}_d) \in \mathbb{R}^{n_b+n_d} : \mathbf{D}_{\boldsymbol{\beta}}(\boldsymbol{\beta}, \boldsymbol{\delta}_d) \succeq \mathbf{0}\} \quad (47)$$

where $\mathbf{D}_{\boldsymbol{\beta}}(\boldsymbol{\beta}, \boldsymbol{\delta}_d) \succeq \mathbf{0}$ is the LMI of $\mathcal{D}_{\boldsymbol{\beta}}$. The new matrix function $\mathbf{D}_{\boldsymbol{\beta}}$ is obtained from (23):

$$\mathbf{D}_{\boldsymbol{\beta}}(\boldsymbol{\beta}, \boldsymbol{\delta}_d) \equiv \mathbf{D}(\mathbf{m}^{-1}(\boldsymbol{\beta}, \boldsymbol{\delta}_d)) \quad (48)$$

where

$$\begin{aligned} \mathbf{m}^{-1}(\boldsymbol{\beta}, \boldsymbol{\delta}_d) &= \mathbf{G}^{-1} \begin{bmatrix} \boldsymbol{\beta} \\ \boldsymbol{\delta}_d \end{bmatrix} \\ &= \mathbf{P}^T \mathbf{G}_K^{-1} \begin{bmatrix} \boldsymbol{\beta} \\ \boldsymbol{\delta}_d \end{bmatrix} \\ &= \mathbf{P} \begin{bmatrix} \mathbf{1} & -\mathbf{K}_d \\ \mathbf{0} & \mathbf{1} \end{bmatrix} \begin{bmatrix} \boldsymbol{\beta} \\ \boldsymbol{\delta}_d \end{bmatrix} \end{aligned} \quad (49)$$

From (47), (41) can then be written as

$$\mathcal{B} = \{\boldsymbol{\beta} \in \mathbb{R}^{n_b} : \exists \boldsymbol{\delta}_d \in \mathbb{R}^{n_d} \mid \mathbf{D}_{\boldsymbol{\beta}}(\boldsymbol{\beta}, \boldsymbol{\delta}_d) \succeq \mathbf{0}\} \quad (50)$$

Equation (50) still includes an existential quantifier over $\boldsymbol{\delta}_d$. Since $\mathbf{D}_{\boldsymbol{\beta}}$ is positive definite and semialgebraic, by Tarski's theorem we know that \mathcal{B} is also semialgebraic and its closed formula exists, not requiring the computation of $\boldsymbol{\delta}_d$. To obtain the closed formula, quantifier elimination can be done using the cylindrical algebraic decomposition method (Collins, 1975). However, this method has double exponential complexity associated with the space dimension. For small planar robots, where the number of inertial parameters can be cut down to four per link, the method is capable of finding the closed-form conditions. However, for a common robot manipulator, the number of parameters grows to several dozens, rendering a computationally intractable problem. Nonetheless, as we will show in the next section, (50) can still be used to verify base parameter feasibility of general robots, referring not to cylindrical algebraic decomposition but to SDP.

4.3. Verification of physical feasibility

From (47) and (50) we can infer that \mathcal{B} is a projection of \mathcal{D}_β onto the β space. Projections of spectrahedra are known to be convex and semialgebraic, but, unlike bijective affine transformations, they do not necessarily conserve a spectrahedral form (Goldman and Ramana, 1995). Even so, such projections, known as semidefinite representable (or SDP representable) sets, still benefit from all the advantages of SDP techniques (Nesterov and Nemirovskii, 1987). In this context, (50) is a semidefinite representation of \mathcal{B} , \mathcal{D}_β is an SDP lift of \mathcal{B} and \mathbf{D}_β is a lifted LMI for \mathcal{B} .

4.3.1. SDP method for base parameter feasibility test (BPFT). A given $\hat{\beta}$ estimation is feasible if at least one solution exists in the space of δ_d , which in conjunction to $\hat{\beta}$ belongs to \mathcal{D}_β (see (47) and (50)). This can be represented as an SDP feasibility problem by

$$\begin{aligned} & \text{find } \delta_d \\ & \text{subject to } \mathbf{D}_\beta(\hat{\beta}, \delta_d) \geq 0 \end{aligned} \quad (51)$$

Problem (51) is easily solved with any standard SDP software. The LMI $\mathbf{D}_\beta(\hat{\beta}, \delta_d) \geq 0$ defines a set in the space of δ_d . If that set is not empty, the SDP software finds one δ_d solution, implying that $\hat{\beta}$ is feasible. If the set is empty, the SDP software finds a certificate of infeasibility. Hence, this formulation can be used directly as a base parameter feasibility test (BPFT) method.

In Figure 1, an example of feasible and infeasible vectors is given, showing sets and their relations.

4.3.2. SDP method for base parameter feasibility correction (BPFC). In addition to the feasibility test, we can develop a base parameter feasibility correction (BPFC) method to find the feasible base parameter vector β' which is closest to a given base parameter solution $\hat{\beta}$. That problem can be formulated as

$$\begin{aligned} & \underset{(\beta, \delta_d)}{\text{minimize}} \quad \|\hat{\beta} - \beta\| \\ & \text{subject to } \mathbf{D}_\beta(\beta, \delta_d) \geq 0 \end{aligned} \quad (52)$$

which is not in SDP form. Nevertheless, problem (52) is equivalent to

$$\begin{aligned} & \underset{(u, \beta, \delta_d)}{\text{minimize}} \quad u \\ & \text{subject to } u \geq \|\hat{\beta} - \beta\|^2 \\ & \quad \mathbf{D}_\beta(\beta, \delta_d) \geq 0 \end{aligned} \quad (53)$$

where u is an upper bound of the square distance. Using the Schur complement condition for positive

definite matrices, the u inequality of (53) can be written as LMI,

$$\begin{aligned} & \|\hat{\beta} - \beta\|^2 \leq u \\ \Leftrightarrow & u - (\hat{\beta} - \beta)^\top (\hat{\beta} - \beta) \geq 0 \\ \Leftrightarrow & \begin{bmatrix} u & (\hat{\beta} - \beta)^\top \\ \hat{\beta} - \beta & \mathbf{1} \end{bmatrix} \succeq 0 \\ \Leftrightarrow & \mathbf{U}_{\hat{\beta}}(u, \beta) \succeq 0 \end{aligned} \quad (54)$$

Therefore, (52) can be reformulated as an SDP problem:

$$\begin{aligned} & \underset{(u, \beta, \delta_d)}{\text{minimize}} \quad u \\ & \text{subject to } \mathbf{F}_{\hat{\beta}}(u, \beta, \delta_d) \geq 0 \end{aligned} \quad (55)$$

where $\mathbf{F}_{\hat{\beta}}(u, \beta, \delta_d)$ is a block-diagonal matrix given by

$$\mathbf{F}_{\hat{\beta}}(u, \beta, \delta_d) = \begin{bmatrix} \mathbf{U}_{\hat{\beta}}(u, \beta) & \mathbf{0} \\ \mathbf{0} & \mathbf{D}_\beta(\beta, \delta_d) \end{bmatrix} \quad (56)$$

With (u', β', δ'_d) being the solution of (55), β' is the physically feasible base parameter vector closest to $\hat{\beta}$ and u' is the respective squared distance. If u' is zero, then $\hat{\beta} = \beta'$ meaning that $\hat{\beta}$ is feasible.

4.4. Optimal estimation of base parameters

In this section we propose an SDP solution to find the base parameters within the feasible space which best fits the regression data. The SDP approach guarantees fast and accurate convergence. One of the methods to identify the dynamic model is to move the robot along an identification trajectory (i.e. an excitation trajectory used for parameter identification), doing regression over joint and torque data (Khalil and Dombre, 2002). Having a trajectory with s points (with $s \gg 1$), the motion data is collected into a regression matrix W and a vector ω , where

$$W \equiv \begin{bmatrix} H_b(q_1, \dot{q}_1, \ddot{q}_1) \\ H_b(q_2, \dot{q}_2, \ddot{q}_2) \\ \vdots \\ H_b(q_s, \dot{q}_s, \ddot{q}_s) \end{bmatrix} \quad (57)$$

and

$$\omega \equiv \begin{bmatrix} \tau_1 \\ \tau_2 \\ \vdots \\ \tau_s \end{bmatrix} \quad (58)$$

The estimated base parameters are the ones that minimize the residuals ϵ in

$$W\beta + \epsilon = \omega \quad (59)$$

Such minimization can be done using ordinary least squares (OLS), minimizing the sum of squared residuals given by

$$\|\epsilon\|^2 = \|\omega - W\beta\|^2 \quad (60)$$

Fig. 1. Relation between feasible sets in the δ , (β, δ_d) and β spaces (2D illustration). $\hat{\beta}_f$ is a feasible parameter vector and $\hat{\beta}_i$ is infeasible. The BPFT method applied to $\hat{\beta}_f$ is able to find a $\hat{\delta}_{df}$ for which $(\hat{\beta}_f, \hat{\delta}_{df})$ is inside the feasibility set \mathcal{D}_β .

The β estimation is the solution of the problem

$$\begin{aligned} & \underset{(u, \beta)}{\text{minimize}} && u \\ & \text{subject to} && u \geq \|\omega - W\beta\|^2 \end{aligned} \quad (61)$$

which, using the Schur complement in a similar way to in (54), can be written as an SDP problem as

$$\begin{aligned} & \underset{(u, \beta)}{\text{minimize}} && u \\ & \text{subject to} && \mathbf{U}_\omega(u, \beta) \succeq 0 \end{aligned} \quad (62)$$

where

$$\mathbf{U}_\omega(u, \beta) \equiv \begin{bmatrix} u & (\omega - W\beta)^T \\ \omega - W\beta & \mathbf{1} \end{bmatrix} \quad (63)$$

The square matrix \mathbf{U}_ω has $sN + 1$ rows, which might be too big for SDP solutions.

4.4.1. SDP method for feasible base parameter estimation with OLS. Given the QR orthogonal-triangular decomposition of the rectangular matrix W ,

$$W = QR = [Q_1 \quad Q_2] \begin{bmatrix} R_1 \\ 0 \end{bmatrix} = Q_1 R_1 \quad (64)$$

it is known that

$$\|Q^T \epsilon\|^2 = (Q^T \epsilon)^T (Q^T \epsilon) = \epsilon^T Q Q^T \epsilon = \epsilon^T \epsilon = \|\epsilon\|^2 \quad (65)$$

since Q is orthogonal. From (60), (64) and (65),

$$\|\epsilon\|^2 = \|Q^T \omega - Q^T W\beta\|^2 = \left\| \begin{bmatrix} Q_1^T \\ Q_2^T \end{bmatrix} \omega - \begin{bmatrix} R_1 \\ 0 \end{bmatrix} \beta \right\|^2 \quad (66)$$

Defining

$$\rho_1 \equiv Q_1^T \omega \quad (67)$$

$$\rho_2 \equiv Q_2^T \omega \quad (68)$$

and

$$\rho \equiv \begin{bmatrix} \rho_1 \\ \rho_2 \end{bmatrix} \quad (69)$$

we get the equivalence

$$\|\epsilon\|^2 = \left\| \begin{bmatrix} \rho_1 \\ \rho_2 \end{bmatrix} - \begin{bmatrix} R_1 \\ 0 \end{bmatrix} \beta \right\|^2 = \|\rho_2\|^2 + \|\rho_1 - R_1 \beta\|^2 \quad (70)$$

where the term $\|\rho_2\|^2$ is not dependent on β . From (60), (61) and (70),

$$u - \|\rho_2\|^2 \geq \|\rho_1 - R_1 \beta\|^2 \quad (71)$$

Hence, the SDP problem of (62) is in fact equivalent to

$$\begin{aligned} & \underset{(u, \beta)}{\text{minimize}} && u \\ & \text{subject to} && \mathbf{U}_\rho(u, \beta) \succeq 0 \end{aligned} \quad (72)$$

where

$$\mathbf{U}_\rho(u, \beta) \equiv \begin{bmatrix} u - \|\rho_2\|^2 & (\rho_1 - R_1 \beta)^T \\ \rho_1 - R_1 \beta & \mathbf{1} \end{bmatrix} \quad (73)$$

The new LMI matrix \mathbf{U}_ρ is square with $n_b + 1$ rows, being much smaller than \mathbf{U}_ω , and therefore computationally tractable.

We can now formulate a method for feasible base parameter estimation with OLS (FBPE-OLS). By including the constraint $\mathbf{D}_\beta(\beta, \delta_d) \succeq 0$ into problem (72), the physically feasible base parameter vector β^* which minimizes the sum of squared residuals is given by

$$\begin{aligned} & \underset{(u, \beta, \delta_d)}{\text{minimize}} && u \\ & \text{subject to} && \mathbf{F}_\rho(u, \beta, \delta_d) \succeq 0 \end{aligned} \quad (74)$$

where

$$\mathbf{F}_\rho(u, \beta, \delta_d) = \begin{bmatrix} \mathbf{U}_\rho(u, \beta) & 0 \\ 0 & \mathbf{D}_\beta(\beta, \delta_d) \end{bmatrix} \quad (75)$$

Fig. 2. Regression with a non-feasible $\hat{\beta}$ (2D illustration). The always feasible and optimal solution β^* has lower regression error than the feasible solution β' closer to $\hat{\beta}$.

The solution to this problem is $(u^*, \beta^*, \delta_d^*)$, where u^* is the sum of squared residuals of (59) with $\beta = \beta^*$. If β^* is equal to the unconstrained estimation $\hat{\beta}$ of (72) then $\hat{\beta}$ is feasible. In this case, β^* is also equal to the solution β' given by (55). If $\hat{\beta} \neq \beta^*$, then $\hat{\beta}$ is infeasible, and the feasible solution β' is not necessarily equal to β^* , as illustrated in Figure 2. The fact that the regression errors of β' and β^* are always bigger than the $\hat{\beta}$ error (when $\hat{\beta}$ is infeasible) does not necessarily mean that such estimations entail worse models. Indeed, the question of whether these estimations are worse or better than physically infeasible ones can be related to the kind of desired model: either a prediction model, seeking the lowest prediction error, or a structural model, seeking a meaningful physical system description (Hollerbach et al., 2008). Although physically infeasible estimations can be acceptable for prediction purposes, such estimations do not meet the physical requirements of structural models, being unsuitable for control and simulation.

4.5. Parameter space issues

The methods BPFT, BPFC and FBPE-OLS have been developed on the base parameter space β plus the null space δ_d . With straightforward algebraic manipulation, it is possible to directly write these methods on the link parameter space δ . The drawback of δ solutions is that they are a mix of identifiable values and null-space values, which contain redundant and arbitrary information. With (β, δ_d) solutions, informative and uninformative terms are split into β and δ_d , respectively. One can still map (β, δ_d) to the δ space through the inverse mapping m^{-1} given by (49). Regarding the non-unique choice of base parameter combinations, feasibility/infeasibility is maintained when mapping between different base parameter spaces. Two base parameter vectors on two different base spaces are equivalent when they share the same virtual parameter set (see (40)). Since feasibility is dependent on the virtual parameter set, both base parameter vectors also share the feasibility/infeasibility property. Therefore, the BPFT method

is invariant with respect to the choice of parameter grouping. Since the regression error of (60) is not affected by base parameter regrouping (a transformation in β implies canceling operations in W), the FBPE-OLS method gives equivalent solutions for different (β, δ_d) spaces. Solutions using the BPFC method are however dependent on parameter grouping. This is due to the fact that the BPFC method is based on measured distances in base parameter space which in general are not linearly mapped between different spaces. Nevertheless, the BPFC method can be applied to correct an infeasible solution for which regression data is no longer available. Moreover, the $\|\hat{\beta} - \beta'\|$ distance given by BPFC can be used as a measurement of infeasibility.

5. Experimental tests

Two applications are presented in this section. The first one addresses the feasibility test of a three-link robot using the BPFT method. The second one analyzes the three methods proposed in this paper using the seven-link WAM robot. The proposed methods were deployed in Python and rely on open-source solutions only. The LMI is first defined by a symbolic matrix using the Python SymPy symbolic library. This allows easy mapping from the δ space to the (β, δ_d) space. Then, referring to the PyLMI-SDP package (available at <https://github.com/cdsousa/PyLMI-SDP>) developed by the authors, the coefficient matrices are extracted from the symbolic LMI and saved into the SDPA sparse file format. This format is accepted by a large number of SDP solvers which directly exploit the sparsity of LMI matrices. For the BPFT method, the 'find' problem of (51) is implemented by setting an objective function equal to zero. In our experiments, the SDP optimization is performed by the DSDP5 solver (Benson and Ye, 2008), which is based on the interior-point method, as many other SDP solvers are. The DSDP5 solver has a tolerance parameter to define the solution accuracy. We set this parameter to 10^{-7} . Additionally, LMI strictness is enforced with a safe margin of $\varepsilon = 10^{-6}$ (see (21)).

5.1. Base parameter feasibility test of a three-link robot

We applied our BPFT and BPFC methods to the example included in Yoshida and Khalil (2000). Yoshida and Khalil introduced a base parameter combination β for a three-link robot and presented two examples of base parameter vector values, $\hat{\beta}_{t1}$ and $\hat{\beta}_{t2}$ (see Table 1).

They have shown that $\hat{\beta}_{t1}$ is feasible and $\hat{\beta}_{t2}$ is not. We double-checked $\hat{\beta}_{t1}$ and $\hat{\beta}_{t2}$ with the BPFT method. For $\hat{\beta}_{t1}$, a δ_d solution is found, which implies physical feasibility. In the case of $\hat{\beta}_{t2}$ a certificate of infeasibility is issued by the SDP solver. These results corroborate the Yoshida and Khalil ones. Furthermore, we applied the BPFC method to $\hat{\beta}_{t2}$ for which the closest feasible parameter vector β'_{t2} is

Table 1. Base parameter estimations of the three-link robot example provided by Yoshida and Khalil (2000).

$\beta(\delta)$	$\hat{\beta}_{t1}$	$\hat{\beta}_{t2}$	β'_{t2}
$L_{1yy} + L_{2yy} + L_{3yy} + m_3$	6.4	6.2	6.200951

3	$-\pi/2$	0.045	0.55	q_3
4	$\pi/2$	-0.045	0	q_4
5	$-\pi/2$	0	0.3	q_5
6	$\pi/2$	0	0	q_6
7	0	0	0.06	q_7

found (see Table 1). The distance from β'_{t2} to $\hat{\beta}_{t2}$, measured in β space, is given by $\sqrt{u'} = 1.65 \times 10^{-3}$. As expected, β'_{t2} passes the BPFT feasibility test. For this example no regression data is available, so the FBPE-OLS method could not be tested.

5.2. Parameter identification of the seven-link WAM arm

We performed experiments with a seven-link robot, the Barrett WAMTM Arm, to test our LMI–SDP methods.² The WAM geometry is described by the Denavit–Hartenberg parameters presented in Table 2.

For identification purposes we consider a dynamic model including joint friction in the form of (27) and drive chain inertia as presented in Dombre (2002). The dynamic model is derived using the author's SymPyBotics software (available at <https://github.com/cdsousa/SymPyBotics>), an open-source Python package for symbolic robot dynamics, based on SageRobotics (Sousa and Cortesão, 2012). With this software, the base inertial parameter combination shown in Table 3 is obtained, yielding 69 base parameters (β) out of 98 link parameters (δ).

To obtain dynamic model regression data, a periodic identification trajectory is performed by the robot.

5.2.1. Computed torque control. Unlike common industrial robots, the WAM robot is controlled directly in torque. The motors are commanded in current by internal current controllers which receive torque set points. The robot has no torque sensors and does not provide access to motor currents. Thus, we assume good torque-to-current conversion and good current tracking control. Torque command allows nonlinear feedback linearization and computed torque control. The trajectory is performed through a proportional and derivative (PD) position controller over the linearized robot

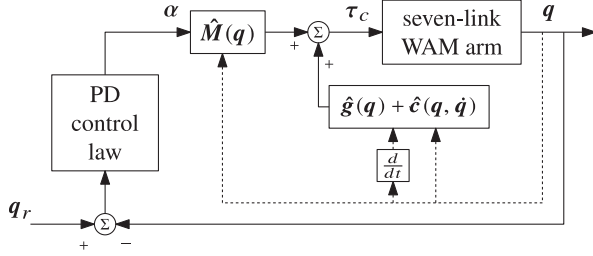

Fig. 3. Proportional and derivative (PD) joint position control scheme of the seven-link WAM arm with feedback linearization; q_r is the joint reference position.

Table 4. PD joint position control gains for the seven-link WAM arm.

Joint k	$K_{p,k}$	$K_{d,k}$
1	400.0	40.0
2	204.1	28.6
3	625.0	50.0
4	400.0	40.0
5	10,000.0	200.0
6	10,000.0	200.0
7	20,408.2	285.7

plant, as shown in Figure 3. The commanded torque τ_c is computed by

$$\tau_c = \hat{g}(q) + \hat{c}(q, \dot{q}) + \hat{M}(q) \alpha \quad (76)$$

where $\hat{g}(q)$, $\hat{c}(q, \dot{q})$ and $\hat{M}(q)$ are estimations of $g(q)$, $c(q, \dot{q})$ based on CAD dynamic parameters, and α is the desired acceleration. For control purposes we do not consider friction or drive inertia. Neglecting dynamic model errors, the plant for each joint k in free space is given by (see (1) and (76))

$$\ddot{q}_k = \alpha_k \quad (77)$$

This is equivalent to a double integrator over which the PD controller is designed. PD gains ($K_{p,k}$ and $K_{d,k}$, respectively) given in Table 4 are tuned for critically damped responses.

5.2.2. Trajectory generation and data processing. The identification trajectory is generated and optimized using the techniques proposed by Swevers et al. (1997). Each k th joint trajectory is defined as a function of time t by

$$q_{r,k}(t) = \sum_{l=1}^L \frac{a_{k,l}}{\omega_f l} \sin(\omega_f l t) - \frac{b_{k,l}}{\omega_f l} \cos(\omega_f l t) + q_{k,0} \quad (78)$$

where, in our experiment,

$$\omega_f = 0.1\pi \quad (79)$$

and

$$L = 5 \quad (80)$$

entailing a period of 20 s. Trajectory parameters $a_{k,l}$, $b_{k,l}$ and $q_{k,0}$ are set to the values shown in Table 5. The reference joint positions for one whole period are shown in Figure 4.

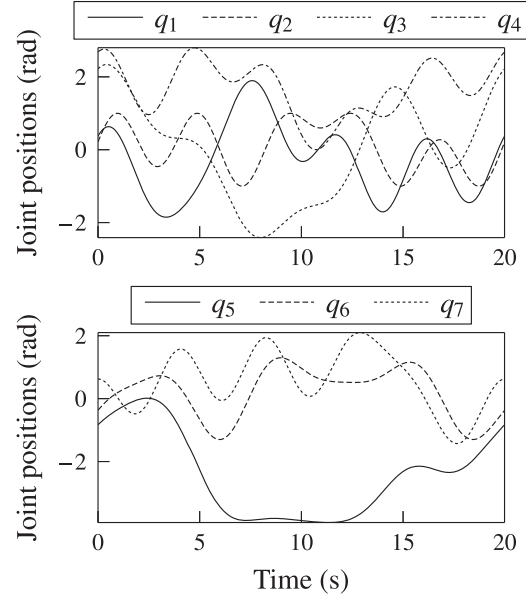

Fig. 4. Identification trajectory for the seven-link WAM arm. Joint position reference for the first period.

The robot performs the identification trajectory for almost 1 min. At a sampling time of 1 ms, a total of $s = 57,656$ trajectory points (joint position and torque) are recorded. Position data comes from encoder readings and torque data comes from the computed torque τ_c (see (76)). Joint position signals are filtered with third-order low-pass Butterworth filters with cutoff frequency $10\omega_f L/2\pi$. This process is done offline, therefore phase distortion is compensated for. First- and second-order derivatives of the position are computed through second-order central differences. Applying the corresponding H_b matrix to the data, the regression matrix W and the torque vector ω are obtained, both with $sN = 403,592$ rows. The regression matrix has a condition number of 99, therefore it can be considered well conditioned (Gautier and Khalil, 1992).

5.2.3. Classical base parameter estimation. Using the identification trajectory data, W and ω , the classical OLS solution $\hat{\beta}$ given in Table 6 is obtained. CAD parameters used in the controller β_{CAD} are also shown in Table 6. The vector of $\hat{\beta}$ standard deviations is computed by the formula (Khalil and Dombre, 2002)

$$\hat{\sigma}_{\hat{\beta}} = \sqrt{\text{diag}(\hat{\sigma}_{\epsilon}^2 (W^T W)^{-1})} \quad (81)$$

where $\hat{\sigma}_{\epsilon}^2$ is the variance of the estimation error ϵ (see (59)) given by

$$\hat{\sigma}_{\epsilon}^2 = \frac{\|\omega - W\hat{\beta}\|^2}{sN - n_b} \quad (82)$$

Table 5. Identification trajectory parameters for the seven-link WAM arm.

The percentage of relative standard deviation of the $\hat{\beta}_k$ k th parameter, given by

$$\% \hat{\sigma}_{\hat{\beta}_k} = \frac{\hat{\sigma}_{\hat{\beta}_k}}{|\hat{\beta}_k|} \cdot 100\% \quad (83)$$

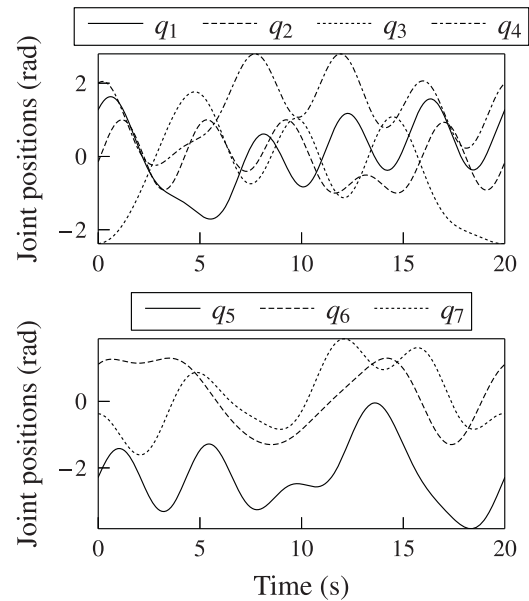

is presented in Table 6.

The solution $\hat{\beta}$ is tested with the BPFT method, set with LMI conditions on both link inertia and drive parameters (see (28)). The SDP solver issues an infeasibility certificate, showing that $\hat{\beta}$ is physically infeasible. For this solution, the inertia matrix $M(q)$ is not positive definite for some random q values, which corroborates physical infeasibility. Moreover, in this particular case, the infeasibility can be directly inferred since some drive inertia parameters are negative.

5.2.4. Feasible base parameter estimations. Since the $\hat{\beta}$ solution is not feasible, its closest feasible vector, β^* , is computed by the BPFC method. We also applied the FBPE-OLS method to the same regression data obtaining the optimal solution β^* . Based on datasheet information, we added extra constraints to the LMI on centers of mass and total mass. Each center-of-mass constraint is of form (26) with bounds given by the smallest cuboid containing link's body (see Table 7). The sum of link masses is constrained to a maximum of 27 kg.

The solution β^* does not pass the feasibility test (BPFT) if these additional constraints are taken into account. Therefore, we reapplied the FBPE-OLS method with the extra constraints obtaining the β^{*c} solution shown in Table 6. The feasibility of each of these solutions is successfully double-checked by analyzing eigenvalue positiveness of the respective LMI matrices. As expected, the inertia matrix evaluated with these solutions at random q is always positive definite.

Regarding computing time performance, the SDP solver running on a mid-end laptop proves to be very fast, taking

**Fig. 5.** Validation trajectory A for the seven-link WAM arm. Joint position reference for the first period.

less than 2 s to find each solution. (For a simulated 20-link robot, the SDP solver takes less than 15 s to obtain the FBPE-OLS solution.)

5.2.5. Estimation assessment. To validate the estimated parameters, three validation trajectories, named A, B and C, are generated by the same techniques used for the identification trajectory, although with different initial conditions. As a result, validation trajectories have the same harmonic frequencies but with unrelated amplitudes (e.g. Figure 5 shows the joint reference for validation trajectory A). The robot performs validation trajectories for about 1 min, and the recorded data is processed in the same way as for the

Table 8. Percentage of relative error ($100\% \cdot \|\omega - W\beta\|/\|\omega\|$) of predicted torque for identification and validation trajectories.

	OLS $\hat{\beta}$	BPFC β'	FBPE-OLS	
			β^*	β^{*c}
Identification	6.60	6.68	6.64	6.65
Validation A	7.16	7.14	7.01	6.98
Validation B	8.47	8.49	8.44	8.40
Validation C	6.81	6.79	6.76	6.74

for all four solutions ($\hat{\beta}$, β' , β^* and β^{*c}). Table 8 presents, in percentages, the relative torque error given by

$$\epsilon_r = \frac{\|\omega - W\beta\|}{\|\omega\|} \quad (84)$$

for both identification and validation trajectories.

For the identification trajectory (first row of Table 8), all four solutions present values of relative error below 7%, indicating good parameter estimation. As expected, physically feasible constrained estimations show higher regression errors than the unconstrained one, $\hat{\beta}$. Also as expected, β^* has less error than β' , and β^{*c} has a higher regression error with respect to β^* . Even so, differences between solutions are small ($< 0.1\%$). The relative prediction errors of validation trajectories (bottom three rows of Table 8) are below 8.5%, indicating good torque prediction as well. Feasible estimations present slightly smaller errors with respect to the classical OLS solution, showing good performance outside the identification set. Figure 6 shows plots of measured torque, β^{*c} predicted torque and respective error for trajectory A.

It can be inferred that for the first four joints predicted torque tracks the measured one well. For the last three joints some degradation occurs due to smaller torque values, since inertial parameters are relatively small. Looking at Table 6, we can also infer that for the last three joints some $\hat{\beta}$ parameters have big $\% \hat{\sigma}_{\hat{\beta}}$, probably indicating bad estimations. This can suggest that a sequential or a weighted least squares (WLS) approach can improve the identification (Gautier, 1997), although it does not guarantee physical feasibility. In this case, FBPE-OLS can be easily modified to accommodate a WLS regression.

identification trajectory. Regressor matrices for validation trajectories A, B and C show good condition numbers of 94, 106 and 101, respectively. Torque prediction is computed

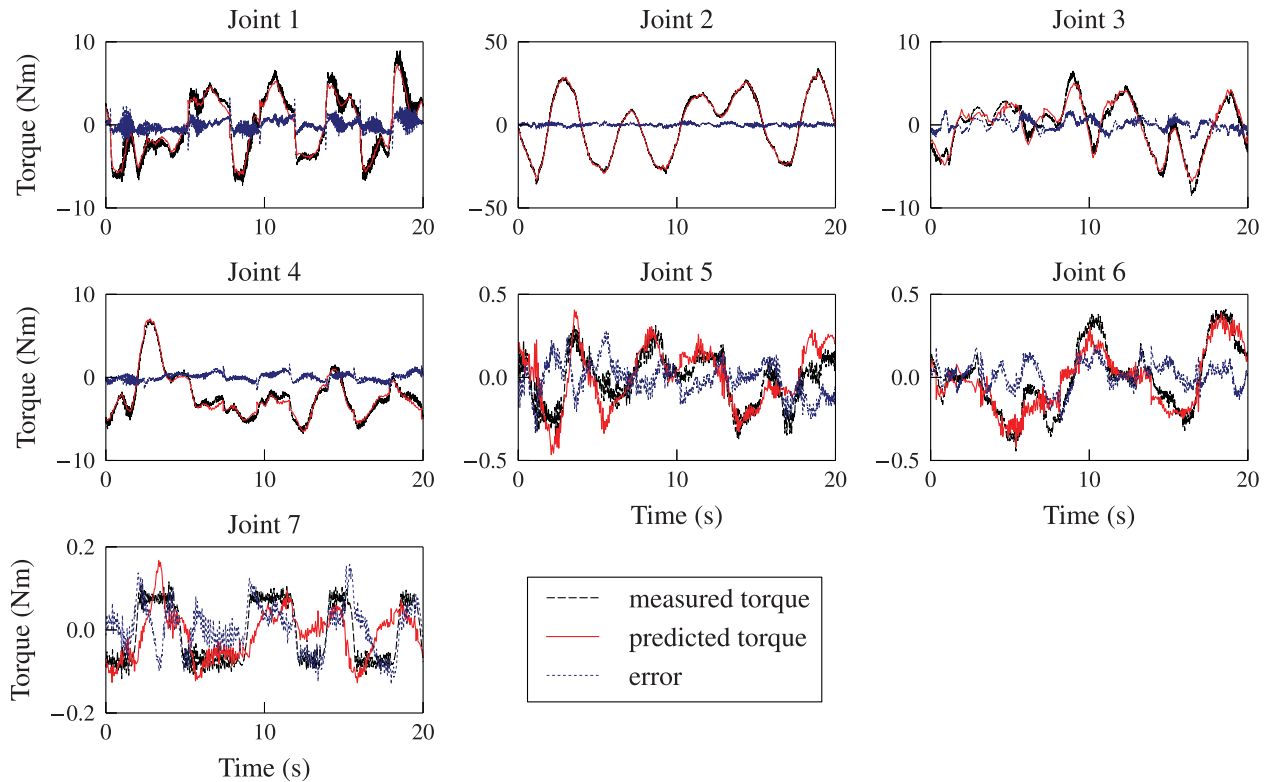

Fig. 6. Validation trajectory A for the seven-link WAM arm. Measured torque vs predicted torque of the β^{*c} solution.

6. Conclusion

In this paper we have presented a systematic approach to address the physical feasibility of estimated robot base inertial parameters. Feasibility conditions have been written with LMIs, ready to be used in the SDP framework. Moreover, feasible sets can be further restricted to cope with additional constraints (e.g. spacial limits on the center of mass and bounded masses) and extended to include additional dynamic parameters (e.g. friction).

We have proposed three LMI-SDP-based methods addressing the physical feasibility of base parameters. The BPFT method tests if a given parameter estimation is physically feasible or not. The BPFC method computes the closest physically feasible solution for a given (infeasible) solution. Finally, the FBPE-OLS method performs optimal estimation of base parameters (for a given data set) through least squares regression constrained to feasible solutions. These methods benefit from SDP advantages, noticeably the efficient convergence to the global optimum. LMI-SDP is well suited to dealing with the feasibility problem, since it is a convex optimization technique which exploits positive semidefinite constraints. The FBPE-OLS method does not require a feasibility cost function definition and deals with base parameter space issues in a straightforward way. The FBPE-OLS is pertinent when model approximation and measurement errors entail infeasible solutions by classical techniques. All three methods address the issue of physically consistent estimations for a given data set and for a

given robot dynamic model. Obviously, better robot models and better data sets entail better solutions. The proposed methods have been assessed using three-link and seven-link robot arms. Seven-link robot feasible estimations have been successfully achieved within the LMI-SDP framework, showing good performance for both identification and validation trajectories. These methods have been straightforwardly implemented with open-source software, being computationally efficient.
